## ABSTRACT

In this paper, we introduce Ant-Miner<sub>MA</sub> to tackle mixed-attribute classification problems. Most classification problems involve continuous, ordinal and categorical attributes. The majority of Ant Colony Optimization (ACO) classification algorithms have the limitation of being able to handle categorical attributes only, with few exceptions that use a discretisation procedure when handling continuous attributes either in a preprocessing stage or during the rule creation. Using a solution archive as a pheromone model, inspired by the ACO for mixed-variable optimization (ACO<sub>MV</sub>), we eliminate the need for a discretisation procedure and attributes can be treated directly as continuous, ordinal, or categorical. We compared the proposed Ant-Miner<sub>MA</sub> against cAnt-Miner, an ACO-based classification algorithm that uses a discretisation procedure in the rule construction process. Our results show that Ant-Miner<sub>MA</sub> achieved significant improvements on computational time due to the elimination of the discretisation procedure without affecting the predictive performance.

## 1. INTRODUCTION

Data mining is the process of extracting knowledge and patterns from data [1, 22]. One of the major data mining areas is classification. Classification is concerned in finding patterns in data sets, then use those patterns to classify any new (future) data. Classification problems can be viewed as optimization problems, where the aim is to create the best model that represent the predictive patterns in

the data. The discovered classification model is then used to classify—predict the class attribute value of—new examples (unseen during training) based on the values of their predictor attributes. Using classification rules gives a more comprehensible classification model compared to black-box models such as SVMs or artificial neural networks [17], which are more difficult to be interpreted.

The first Ant Colony Optimization (ACO) classification algorithm, called Ant-Miner, was proposed in [16]. Ant-Miner and its extensions [7] were used to successfully extract *IF-THEN* classification rules from data. Each ant traverses a construction graph, where each node in the graph consists of a condition that the ant might choose to add to its rule. The majority of ACO-based classification algorithms are limited to cope only with categorical attributes, therefore continuous attributes must be discretised in a pre-processing stage. cAnt-Miner [13, 14] was the first Ant-Miner extension to cope with continuous attributes directly. It employs a dynamic discretisation procedure during the rule construction: when an ant select a node representing a continuous attribute, the discretisation procedure is used to determine cutoff value in a dynamic manner. A potential drawback of this approach is its computational time: discretisation requires sorting and the evaluation of multiple candidate cutoff values, which can significantly increase the computational time of the algorithm when applied to large data sets.

In this paper we propose a new approach to extract *IF-THEN* of classification rules, based on the ACO for mixed-variable optimization (ACO<sub>MV</sub>) [3]. Our approach handles the mixed attributes directly: attributes are categorized as continuous, ordinal and categorical attributes. This takes full advantage of the mechanisms of ACO<sub>MV</sub> to tackle mixed-variable optimization to cope with mixed-attribute classification problems. More importantly, it eliminates the need for a discretisation procedure, which improves the computational time for most of the large datasets. We compared the predictive accuracy and computational time performance of the proposed algorithm against cAnt-Miner in 30 publicly available data sets. Our results show that the proposed algorithm significantly improves the computational time when compared to cAnt-Miner while maintaining the predictive accuracy.

The remainder of this paper is organized as follows. We begin by reviewing the literature of ACO-based classification algorithms in Section 2. Then, we present an overview of cAnt-Miner and ACO<sub>MV</sub> in Section 3. We then present our proposed Ant-Miner<sub>MA</sub> algorithm in Section 4, com-

putational results are presented in Section 5, and finally, conclusions and directions for future work are discussed in Section 6.

## 2. RELATED WORK

There are two main approaches to apply ant colony optimization to create classification rules: grammar- and graph-based approaches. In grammar-based approaches, the rule creation is guided by a context-free grammar, which determines the valid structure of rules. The Grammar-Based Ant Programming (GBAP) algorithm [9, 10] was the first implementation of a grammar-based approach. Similar to most of ACO-based classification algorithms, GBAP does not cope with continuous attributes directly and it uses a discretisation procedure in a preprocessing stage.

Graph-based approaches started with Ant-Miner [16], which was limited to discrete datasets only. Several extensions of Ant-Miner have been proposed [7]. Ant-Miner2 [6] and Ant-Miner3 [5] presented a simple heuristic function using density estimation. Ant-Miner+ [8] extended Ant-Miner in several aspects: it uses a class based heuristic, since an ant pre-selects the predicted class value and extracts a rule accordingly; it also employs a different pheromone initialization and update procedure based on  $MAX - MIN$  ant system ( $MMAS$ ) [21], where the use of the lower and upper bound values allows the algorithm to avoid early stagnation of the search; and the complexity of the construction graph is reduced, in terms of the number of edges connecting vertices, by defining it as a direct acyclic graph (DAG).

Additionally, Ant-Miner+ employs a distinctive procedure for categorical and ordinal attributes. Categorical attributes have unordered nominal values (e.g., *male* and *female*), which were treated as a tuple (*attribute*, =, *value*). Ordinal attributes have a natural order (e.g., *poor* < *acceptable* < *good*), where the algorithm creates upper and lower bounds on the values chosen by the ant: the first type represents a lower bound of the interval and takes the form (*attribute*, ≤, *value<sub>i</sub>*); the second type represents an upper bound of the interval and takes the form (*attribute*, ≥, *value<sub>j</sub>*), where *value<sub>i</sub>* and *value<sub>j</sub>* are values from the attribute domain. Continuous attributes are discretised in a pre-processing stage and then treated as ordinal attributes.

*cAnt-Miner* was proposed in [13], where an entropy-based method is proposed for handling the continuous attributes discretisation during the rule construction process. The use of the minimum description length (MDL) principle in *cAnt-Miner* to allow construction of discrete intervals with lower and upper bounds was proposed in [14]. Further improvements in the *cAnt-Miner* are found in [18], where the authors proposed the use of multiple pheromone levels to extract rules predicting different class values. The latest improvements based on *cAnt-Miner* were presented in [15], where using a new sequential covering strategy, each ant creates and evaluates a rule list (considering interactions among rules) rather than creating and evaluating a single rule like most versions of Ant-Miner. More recently, an extension to discover unordered rules (set of rules) instead of ordered rules (list of rules), with the aim of improving the interpretability of the discovered rules, was proposed in [11, 12].

Despite the Ant-Miner extensions proposed in the literature, extending Ant-Miner to use a archive-based pheromone model to handle continuous and categorical values (i.e., using  $ACO_{MV}$  model) is a research topic that has not been

explored, to the best of our knowledge. Most of the proposed extensions handle continuous attributes in a pre-processing stage, while *cAnt-Miner* employs a dynamic discretisation procedure using a heuristic to define intervals.

## 3. BACKGROUND

### 3.1 *cAnt-Miner*

*cAnt-Miner* uses a graph-based approach to extract *IF-THEN* classification rules from data. Let  $r$  be a rule, each rule is a  $n$ -dimensional vector of terms  $t$  that are joined with *AND*, such that *IF*  $t_1$  *AND*  $t_2$  ... *AND*  $t_n$  *THEN* (*class*), each term  $t_i$  consist of a tuple (attribute, operator, value).

The *cAnt-Miner* construction graph consists of a fully connected graph. Let  $a_i$  be a nominal attribute and  $v_{ji}$  be the  $j$ -th value of  $a_i$  attribute. For  $j = 1, \dots, b_i$ , where  $b_i$  is the number of values of attribute  $a_i$ , each  $v_{ji}$  is added as a node ( $a_i, =, v_{ji}$ ) to the graph. Let  $c_i$  be a continuous attribute, only one node is added with ( $c_i$ ) to the graph—the operator and value are not defined for a continuous attribute node.

Suppose an ant  $x$  is generating a rule  $r_x$ . It starts with an empty rule at node  $i$  and probabilistically chooses to visit a node  $j$  based on the amount of pheromone and heuristic information on the edge  $E_{ij}$ , given by

$$P(E_{ij}) = \frac{\tau_{ij}^\alpha \cdot \eta_j^\beta}{\sum_{l \in \text{allowed } i} \tau_{il}^\alpha \cdot \eta_l^\beta} \quad (1)$$

where  $\tau_{ij}$  is the pheromone value of the edge connecting node  $i$  to node  $j$ ;  $\eta_j$  is the value of the heuristic information for node  $j$ ; node  $l$  is a node in the neighbourhood of node  $i$ ; the exponents  $\alpha$  and  $\beta$  are used to control the influence of the pheromone and heuristic information, respectively.

If a node with a nominal attribute is selected, then a term in the form ( $a_i = v_{ij}$ ) is added to the rule. If a node with a continuous attribute is selected, then a dynamic discretisation procedure based on the entropy measure is used to choose an operator and value to create a term in the form ( $a_i \leq v_{ij}$ ) or ( $a_i > v_{ij}$ ). This is done with a complexity of  $O(n \log n)$ , where  $n$  is the number of the training instances, since the values need to be sorted and multiple cutoff values are evaluated.

An ant keeps adding terms until the rule covers less training examples than a user specified threshold, or all attributes are already added to the rule.

### 3.2 $ACO_{MV}$

$ACO_{MV}$  [3] is applied to mixed variables optimization problems with  $r$  real-valued variables,  $c$  categorical-valued variables and  $o$  ordinal-valued variables. The  $ACO_{MV}$  uses a solution archive (SA) as a form of pheromone model, instead of a pheromone matrix. The archive structure contains  $R$  previously generated solutions. Each solution  $S_j$  in the archive, for  $j = \{1, 2, \dots, R\}$ , is a vector containing  $n$ -dimensional real-valued components,  $m$ -dimensional index-valued components and  $o$ -dimensional ordinal-valued components. The archive is sorted by the quality  $Q$  of solutions, so that  $Q(S_1) \geq Q(S_2) \geq \dots \geq Q(S_R)$ .

Each solution  $S_j$  is associated with weight  $w_j$  that is related to  $Q(S_j)$ , where  $w_j$  is calculated using the Gaussian function given by

$$w_j = \frac{1}{qR\sqrt{2\pi}} e^{\frac{-(rank(j)-1)^2}{2q^2R^2}} \quad (2)$$

where  $q$  is a variable that is used to control the extend of the top-ranked solution influence on the construction of new solutions. The weight of solution  $S_j$  is used during the creation of new solutions, as an indicator for the level of attractiveness of this solution. The higher the weight of the solution  $S_j$ , the higher the probability of sampling a new solution around the values of  $S_j$ .

ACO<sub>MV</sub> starts by randomly generating  $R$  solutions in the archive. The solution construction phase starts by each ant  $i$  generating a new  $S_i$  candidate solution. When constructing solution  $S_i$ , a probabilistic solution construction method is used to sample new values from the solution archive according to each attribute type. At the end of an iteration, all solutions created by the ants in the colony are added to the archive. The archive is sorted and only the best  $R$  solutions are kept and the remaining solutions are removed.

### 3.2.1 Continuous variables

Continuous variables are handled by ACO<sub>MV</sub> using ACO<sub>R</sub> [19], where each ant  $i$  probabilistically chooses one solution from the archive based on

$$P_j = \frac{w_j}{\sum_{l=1}^R w_l} \quad (3)$$

where  $P_j$  is the probability of selecting the  $j$ -th solution from the archive to sample the new continuous variable value around it,  $R$  is the size of the archive, and  $w_j$  is the weight associated with the  $j$ -th solution in the archive. Let  $S_i$  denote a new solution sampled by ant  $i$  around the chosen solution  $S_j$  for continuous attribute  $a$ , the Gaussian probability density function (PDF) is given by

$$S_{i,a} \sim N(S_{j,a}, \sigma_{j,a}) \quad (4)$$

$$\sigma_{j,a} = \xi \sum_{r=1, r \neq j}^R \frac{|S_{j,a} - S_{r,a}|}{R-1} \quad (5)$$

where  $S_{j,a}$  is the value of the variable  $a$  in the solution  $j$  of the archive,  $\sigma_{a,j}$  is the average distance between the value of the variable  $a$  in the solution  $j$  and the value of  $a$  in all the other solutions in the archive and  $\xi$  is a user-defined value representing the convergence speed of the algorithm.

### 3.2.2 Ordinal variables

Ordinal variables are variables whose order have a meaning, e.g., *small* < *medium* < *large*. ACO<sub>MV</sub> handles ordinal variables as continuous variables, where the continuous value is the index of the chosen value in the ordered attribute values. Then, a final step is to round up the value generated from Equation (4) to the nearest index. Using this relaxed continuous sampling allows the algorithm to take in consideration the order of the attribute values.

### 3.2.3 Categorical variables

Categorical variables are treated differently by ACO<sub>MV</sub>. Suppose a categorical variable  $i$  that has  $t$  possible values,

each ant has to choose  $v_l$  where  $v_l^i \in \{v_1^i, v_2^i, \dots, v_t^i\}$ . The probability  $P_l^i$  to choose  $v_l$  is given by

$$P_l^i = \frac{\alpha_l}{\sum_{l=1}^t \alpha_l} \quad (6)$$

where the variable  $\alpha_l$  is weight function for each value of the categorical variable, based on the weight of the solution, calculated as

$$\alpha_l = \begin{cases} \frac{w_{ji}}{u_j} + \frac{q}{\kappa}, & \text{if } \kappa > 0, u_j > 0, \\ \frac{w_{ji}}{u_j}, & \text{if } \kappa = 0, u_j > 0, \\ \frac{q}{\kappa}, & \text{if } \kappa > 0, u_j = 0, \end{cases} \quad (7)$$

where  $\alpha_l$  represents the weight associated with  $v_l$ ,  $w_{ji}$  is the weight of the first solution that uses the value  $v_j$  in the archive,  $u_j$  is the number of solutions that use the value  $v_j$  in the archive,  $\kappa$  is the number of values in this attribute that are not used in the archive, and  $q$  is a variable that is used to control the extend of the top-ranked solution influence on the construction of new solutions.

The categorical sampling procedure allow an ant to consider two components when sampling a new value. The first component biases the sampling towards values that are used in high-quality solutions but do not occur very frequently in the archive. The second component biases the sampling towards unexplored values in that attribute.

## 4. MIXED-ATTRIBUTES IN ANT-MINER

The proposed algorithm Ant-Miner<sub>MA</sub> uses an ACO<sub>MV</sub> procedure to handle mixed attributes types, eliminating the need of an entropy-based discretisation when handling a continuous attribute, and also coping with ordinal attributes. The archive is used to sample conditions for the creation of the rules instead of traversing a construction graph. A high-level pseudocode of Ant-Miner<sub>MA</sub> is shown in Algorithm 1.

Ant-Miner<sub>MA</sub> starts with an empty list of rules (line 1), and iteratively (*outer while loop* in line 2) adds the best rule found along the iterative process to the list of rules (line 20), while the number of uncovered training examples is greater than a maximum uncovered value in a sequential covering fashion.

At each iteration, a single rule is created by an ACO<sub>MV</sub> procedure (lines 3–18). It starts by initializing the archive with  $R$  random generated rules (line 3). Then, each ant generates a new rule (lines 6–11). Once  $m$  new rules have been generated, where  $m$  is the number of ants, they are added into the solution archive (line 12). The  $R$  and  $m$  rules are sorted and the  $m$  worst ones are removed from the archive. The procedure to create a new rule is repeated until the maximum number of iterations has been reached, or a restart procedure is once applied.

### 4.1 Archive and Rule Structure

As aforementioned, the archive consist of  $R$  rules. Each rule consist of a vector of  $n$ -dimensional terms, where  $n$  is the number of attributes in the dataset. Each term  $t_j$  in rule  $R_i$  contains a flag to indicate if this term is enabled or not, an operator and value(s). For continuous attributes, the operator could be either LESS THAN OR EQUAL, GREATER THAN or IN RANGE; categorical attributes' operator is always

	Continuous attribute ( $A_r$ )						Categorical attribute ( $A_c$ )						Ordinal attribute ( $A_o$ )

EQUAL; and ordinal attributes have an operator of either LESS THAN OR EQUAL or GREATER THAN OR EQUAL.

Figure 1 illustrates a solution archive with 3 solutions, each solution showing a single example of each attribute type. The solutions are stored according to their quality in the archive, where the best is stored at the top (highest ranking) and the worse at the bottom (worst ranking). The archive stores the quality of each rule in  $f(S)$  and the weight in  $w$  calculated by Equation (2).

In Figure 1,  $A_r$  is an example of a real-valued (continuous) attribute in the dataset,  $A_c$  is an example of a categorical attribute in the dataset and  $A_o$  is an example of an ordinal attribute in the dataset. The solution  $S_1$  is an

example in which the continuous attribute  $A_r$  is enabled (Flag = T), the operator is GREATER THAN and value  $v_1$  is set—representing the term  $A_r > v_1$ . The categorical attribute  $A_c$  is enabled (Flag = T), the default operator is EQUAL and value  $v_2$  is set—representing the term  $A_c = v_2$ . The ordinal attribute  $A_o$  is not enabled (Flag = F) and so it has no values for operator and value.

The solution  $S_2$  is an example in which the continuous attribute  $A_r$  is enabled (Flag = T), the operator is IN RANGE and two values  $v_3$  and  $v_4$  are set—representing the term  $v_3 \leq A_r < v_4$ . The categorical attribute  $A_c$  is not enabled showing (Flag = F) and so it has no values for operator and value. The ordinal attribute  $A_o$  is enabled (Flag = T), the operator is LESS THAN OR EQUAL and value  $v_5$  is set—representing the term  $A_o \leq v_5$ . Solution  $S_3$  follows a similar representation.

## 4.2 Archive Initialization

In the archive initialization procedure, each rule is randomly initialized. Rule initialization starts with an unbiased random probability to enable each the term, then according to its type it continues the rule initialization. If it is a continuous term, it uses an unbiased random probability to set the operator from the set {LESS THAN OR EQUAL, GREATER THAN, IN RANGE}. The value of the continuous attribute is generated using a random value from a normal distribution in the range of values of the attribute. In case of the IN RANGE operator, two values are generated and the values will only be accepted if they make the operator valid.

Ordinal terms also use an unbiased random probability to choose the operator from the set {LESS THAN OR EQUAL, GREATER THAN OR EQUAL}, then an unbiased random value for the index is generated. For categorical terms, a default EQUAL operator is added, then an unbiased random value for the index is generated.

After the random initialization of each rule, a rule is pruned to remove irrelevant terms enabled by the stochastic nature of the initialization. Then, if the number of covered instances is greater or equal to the user-defined minimum limit, it will be added to the archive. Finally, the rules in the archive are ordered according to their quality, so that  $f(S_1) \geq f(S_2) \geq \dots \geq f(S_R)$ .

### 4.3 Rule Creation

Rule creation follow the following steps:

1. For each term, we start by considering the probability to include the term or not. The decision is handled as a categorical variable, since we are dealing with boolean  $\{\text{TRUE}, \text{FALSE}\}$  values. We use the same procedure in Section 3.2.3 to probabilistic sample a boolean value.
2. If the term is enabled, we set the operator according to the attribute type. If the attribute type is categorical, we set the operator to **EQUAL**. If it is continuous, the decision is handled as a categorical attribute of three values  $\{\text{LESS THAN OR EQUAL}, \text{GREATER THAN}, \text{IN RANGE}\}$ , using the same procedure in Section 3.2.3 to probabilistic sample an operator based on the subset of the archive rules that have this term enabled. While for ordinal attributes, the decision is handled as a categorical attribute of two values  $\{\text{LESS THAN OR EQUAL}, \text{GREATER THAN OR EQUAL}\}$ , using the same procedure in Section 3.2.3 to probabilistic sample an operator based on the subset of the archive rules that have this term enabled.
3. The value of each attribute is then sampled. If the attribute type is continuous, we use the continuous sampling procedure in Section 3.2.1 based on the subset of the archive rules that have this term enabled and using the same operator. If the attribute is ordinal, we use the continuous sampling procedure in Section 3.2.2 to benefit from the order of the attribute, based on the subset of the archive rules that have this term enabled and using the same operator. While for categorical terms we use the discrete sampling procedure in Section 3.2.3 based on the subset of the archive terms that are enabled.
4. After the creation of each term, we apply the rule to the training set. If the rule covered less than the minimum instances, the term is disabled. If it covers more than the minimum instances, the term is added and the process is repeated for the next term, until all terms are considered.

### 4.4 Rule Pruning

Ant-Miner<sub>MA</sub> applies different heuristics for the rule refinement and rule selection following a similar approach proposed in [20]. We use the  $m$ -estimate measure in the rule selection and archive ordering, given by

$$Q = \frac{TP + m \cdot (\frac{P}{P+N})}{TP + FP + m} \quad (8)$$

where  $TP$  and  $FP$  are number of the correct classified and misclassified instances by the rule, respectively;  $P$  and  $N$  are the total number of instances that are in the positive and negative class in training dataset, respectively.<sup>1</sup> The value  $m = 22.466$  used in our approach has been determined experimentally in [2] to be optimum value for the  $m$ -estimate measure.

For the pruning function, we use the sensitivity specificity function, as employed in Ant-Miner, given by

<sup>1</sup>An instance is considered negative if it is from a class different than the class predicted by the rule

**Table 1: Parameters:** Ant-Miner<sub>MA</sub> uses the first three parameters in table, while remaining are used by both Ant-Miner<sub>MA</sub> and cAnt-Miner.

Parameters	Value
$q$	0.025495
$\xi$	0.6795
$R$	90
Minimum Covered	10
Max Uncovered	10
Max Iterations	1500
Number of Ants	60
Stagnation Test	10

$$Q_{Pruning} = \frac{TP}{TP + FN} \cdot \frac{TN}{FP + TN} \quad (9)$$

where  $TP$ ,  $FP$ ,  $TN$  and  $FN$  stand for true positives, false positives, true negatives and false negatives, respectively.

The pruning function starts by disabling the last term in the rule and if the quality of the rule does not decrease, it permanently removes the term; this process is repeated to disable the next one until disabling a term decreases the quality of the rule or the rule has only one term enabled. In this case, the pruning stops, returning the rule without removing the last term. This is the same pruning procedure used by cAnt-Miner [14].

### 4.5 Restart Strategy

Ant-Miner<sub>MA</sub> uses a simple restart strategy to avoid stagnation. The restart strategy is triggered if the best rule of the current iteration is exactly the same as the best rule constructed by a user defined number of previous iterations, which works as stagnation test. When the restart strategy is triggered, all the rules in the archive are reinitialized except the best-so-far rule. The restart is performance only once.

## 5. COMPUTATIONAL RESULTS

Our computational results are calculated using 30 publicly available dataset from the UCI Machine Learning Repository [4], presented in Table 2. Ant-Miner<sub>MA</sub> uses the first three parameters in Table 1 for the archive settings, while the rest of the parameters are used by both Ant-Miner<sub>MA</sub> and cAnt-Miner. The archive settings parameters were empirical chosen based on preliminary experiments. The remaining parameters were based on cAnt-Miner default values [14]. The cAnt-Miner implementation used in the experiments is cAnt-Miner<sub>2MDL</sub> [14]<sup>2</sup>, which can create intervals with lower and upper bounds for continuous attributes.

We ran both algorithms for 15 times in a tenfold cross-validation settings, the average results (over the 150 individual runs) are shown in Table 3. We ran Wilcoxon rank sum test on the 30 datasets to show if there are statistically significant differences in terms of both predictive accuracy and computational time. For a fair comparison, both algorithms are implemented in Java running on the same environment.

<sup>2</sup>We used the cAnt-Miner<sub>2MDL</sub> variation available from <https://github.com/febo/myra>.

**Table 2: Summary of the datasets used in the experiments: datasets from 1 to 18 are considered small datasets, while the remaining ones are considered large datasets due to either the large number of attributes or the large number of instances.**

#	Dataset	Size	#Classes	Attributes

27	diabetes	101766	3	47	2	34	11
28	SkinNonSkin	245057	2	3	0	0	3
29	ForestType	581012	7	54	0	44	10
30	PokerHand	1025010	10	10	5	0	5

Table 3 shows that Ant-Miner<sub>MA</sub> has a higher average rank of 1.43 for the predictive accuracy, where *cAnt-Miner* has an average rank of 1.57. In terms of computational time, Ant-Miner<sub>MA</sub> has a rank of 1.10, while *cAnt-Miner* has a rank of 1.87. Most of the datasets show an order of magnitude improvement of Ant-Miner<sub>MA</sub> over *cAnt-Miner* in terms of computational time. Considering both number of attributes and instances size, the largest datasets are *forest type*, *poker hand* and *diabetes*, respectively. Most notably, *cAnt-Miner* running a single *diabetes* execution takes up to 3.5 days, while Ant-Miner<sub>MA</sub> takes just over 1 hour. Ant-Miner<sub>MA</sub> would take 45 minutes for a single run in *poker hand*, while *cAnt-Miner* almost 8 hours. These results show that the use of the solution archive as pheromone model does not affect the accuracy, while improving the computational time since the discretisation procedure can be eliminated.

Our approach seems to show a small limitation when the number of attributes increases over 50, where we could observe an improvement in computational time of only around 25% in *forest type* dataset. In cases where there is a large number of attributes but a smaller number of instances—which means that the discretisation overhead is less notice-

able—such as in the datasets *Nomao* (119 attributes, 34465 instances), *Hill Valley* (101 attributes, 1212 instances) and *Mice Protein* (81 attributes, 1080 instances), Ant-Miner<sub>MA</sub> running time increases in relation to *cAnt-Miner*. We hypothesised that this is due to the use of heuristic information in *cAnt-Miner*, which allows the algorithm to quickly identify irrelevant attributes and not use them in the rule creation process.

Table 4 indicates that there is no statistically significant differences between Ant-Miner<sub>MA</sub> and *cAnt-Miner* in term of predictive accuracy ( $p = 0.24200$ ). In the case of computational time, Ant-Miner<sub>MA</sub> improvement is statistically significant ( $p = 0.00036$ ). Overall, we consider these results positive. The use of a rule creation process inspired by ACO<sub>MV</sub> led to a statistically significant computational time improvement in Ant-Miner<sub>MA</sub> compared to *cAnt-Miner*, without affecting the predictive accuracy.

## 6. CONCLUSION

We introduced Ant-Miner<sub>MA</sub> to tackle mixed-attribute classification problems, based on ACO<sub>MV</sub>. The use of a solution archive allows the algorithm to deal with categor-

**Table 3: Average predictive accuracy and computational time (average [standard deviation]) of *cAnt-Miner* and *Ant-Miner<sub>MA</sub>* over 15 runs of tenfold cross-validation. The last row of the table shows the average rank of the algorithm. The best value of a given dataset is shown in bold.**

\* Result of a single tenfold execution due to high computational time.

**Table 4: Wilcoxon rank sum tests (at the  $\alpha = 0.05$  level) on predictive accuracy and computational time. Statistically significant differences are shown in bold.**

	Size	W+	W-	Z	<i>p</i>
Accuracy	30	289.5	175.5	-1.1724	0.24200
Time	30	59	406	-3.5686	<b>0.00036</b>

ical, continuous and ordinal attributes directly, without required a discretisation procedure. The rule creation then uses *ACO<sub>MV</sub>* strategies to sample values for each attribute to create the antecedent of a rule.

We compared *Ant-Miner<sub>MA</sub>* against *cAnt-Miner* using publicly available datasets, an ACO-based classification algorithm capable of dealing with continuous attributes using a dynamic discretisation procedure. Our results show that the proposed *Ant-Miner<sub>MA</sub>* statistically significantly improves

the computational time of the algorithm with no negative effects on its accuracy—in most cases, an order of magnitude improvements were observed. This would enable *Ant-Miner<sub>MA</sub>* to be applied to much larger datasets, mitigating the restriction on computational time.

There are several interesting directions for future research. First, it would be interesting to further investigate the effect of the number of attributes in the rule creation process. Our current results indicates that a large number of attributes might affect *Ant-Miner<sub>MA</sub>* computational time. Second, *ACO<sub>MV</sub>* does not provide an explicit mechanism to incorporate heuristic information, which can be used to quickly identify irrelevant attributes. Therefore, incorporating heuristic information into *Ant-Miner<sub>MA</sub>* can potentially improve its computational time by allowing the algorithm quickly identify irrelevant attributes. In addition, an extension to create a complete list of rules instead of one rule at a time is a research direction worth further exploration.
